Abstract

Male ithomiine butterflies (Nymphalidae: Danainae) have hairpencils on the forewings (i.e. androconia) that disseminate semiochemicals during courtship. While most ithomiines are known to contain derivatives of pyrrolizidine alkaloids, dihydropyrrolizines or γ-lactones in these androconia, here we report on a new class of fatty acid esters identified in two subspecies, *Ithomia salapia aquinia* and *I. s.*
**derasa**. The major components were identified as isoprenyl (3-methyl-3-butenyl) \((Z)\)-3-acetyloxy-11-octadecenoate, isoprenyl \((Z)\)-3-acetyloxy-13-octadecenoate \((12)\) and isoprenyl 3-acetyloxyoctadecanoate \((11)\) by GC/MS- and GC/IR-analyses, microderivatizations, and synthesis of representative compounds. The absolute configuration of \((12)\) was determined to be \(R\). The two subspecies differed not only in the composition of the ester bouquet, but also in the composition of more volatile androconial constituents. While some individuals of \(I.\ s.\ aquinia\) contained ithomiolide A, a PA derived \(\gamma\)-lactone, \(I.\ s.\ derasa\) carried the sesquiterpene \(\alpha\)-elemol in the androconia. These differences might be important for the reproductive isolation of the two subspecies, in line with previously reported low gene exchange between the two species in regions where they co-occur. Furthermore, the occurrence of positional isomers of unsaturated fatty acid derivatives indicates activity of two different desaturases within these butterflies, \(\Delta9\) and \(\Delta11\), which has not been reported before in male Lepidoptera.

**Introduction**

The Neotropical butterfly tribe Ithomiini (Nymphalidae: Danainae) is very diverse and species rich, with over 390 species and 50 genera [1, 2]. The largest known radiation of mimetic butterflies, ithomiines are chemically defended and extensively involved in Müllerian mimetic interactions [3], whereby defended species converge in wing color pattern, which acts as a warning signal to predators. Ithomiines are well suited for studies on speciation (species formation), as species often consist of multiple
subspecies diverging for a number of adaptive traits, such as color pattern or host plants, which can then cause reproductive isolation. As such, they offer an excellent system to study the mechanisms underlying diversification and species recognition. Yet despite growing interests in this tribe, chemical differentiation between taxa has garnered surprisingly little attention until now.

Here we focus on the two closely related taxa, *Ithomia salapia aquinia* and *I. s. derasa*. The two subspecies have somewhat divergent wing color patterns (see Supporting Information, Figure S1) [4], are locally abundant, widely distributed, and are parapatric in north-eastern Peru (San Martin) [5]. Despite the geographic overlap in distribution, a recent genetic study showed limited gene flow [4]. Reproductive isolation in mimetic butterflies can be driven by multiple factors, notably non-random mating based on color pattern and/or sexual pheromones [6–8]. Determining whether the closely related subspecies of *I. salapia* differ in their chemical composition is therefore of great interest.

All male ithomiine butterflies, including *Ithomia*, possess scent glands on their forewings, so-called androconia, covered with erectable hairpencils (Figure 1). They are used during courtship and are known to contain compounds acting as pheromones for the butterflies [2]. Adult ithomiines sequester pyrrolizidine alkaloids (PAs) pharmacophagously from various plants [9]. These alkaloids are converted into the alkaloid and pheromone precursor lycopsamine (1) [10–12], which can then be converted either into necine base derived compounds such as methyl hydroxydanaidoate (2), or into necic acids derived ones, e. g. ithomiolide A (3) [13–15]. While dihydropyrrolizines are also used by other Lepidoptera, e. g. danaines [16–18] or arctiines [19, 20], γ-lactones derived from necic acids are specific to ithomiines. They occur in more derived taxa, probably correlated to the recruitment of an oxidase that allows terminal methyl oxidation [14].

Scheme 1: Pyrrolizidine alkaloid lycopsamine (1) and the putative pheromone compounds methyl hydroxydanaidoate (2) and ithomiolide A (3).

Past studies of the androconia of *Ithomia* have reported the presence of 3 in *Ithomia iphinassa* from Venezuela [13] and in *I. salapia salapia* from Ecuador [14], whereas no PA-derived compounds were found in *I. agnosia agnosia* [14]. Necine base derived compounds such as 2 have not been reported for *Ithomia*. Information on constituents other than PA derived compounds in the androconia of Ithomiines are largely unknown,
although we recently described (Z)-9-hydroxy-6-nonenoic acid and derivatives including dimers and fatty acid conjugates as major constituents of the chemical profile of another ithomiine species, _Oleria onega_. In this co-occurring species, androconia lacked PA-derived compounds except for traces of 1-methylene-1H-pyrrolizine [21]. Here we focus on androconial constituents found in males of two subspecies of _I. salapia, I. salapia aquinia_ and _I. salapia derasa_. Investigating androconial constituents in _I. salapia_ can therefore reveal whether the two subspecies differ in their chemical bouquet or not.

Here we report on the chemical composition of the androconia of _Ithomia salapia aquinia_ and _I. s. derasa_. A new type of butterfly androconial constituents, acylated Isoprenyl esters of fatty acids, is described, and is the result of a combination of fatty acid and terpene biosynthesis. We also reveal small but reproducible differences between the two subspecies that could potentially be involved in species recognition and reproductive isolation.

**Results**

Extracts from the wing androconia of _I. s. derasa_ and _I. s. aquinia_ were analyzed by GC/MS. The extracts consisted of predominately fatty acid esters with few other compounds (Table 1). While most ithomiines possess PA-derivatives in the androconia [13–15, 21, 22], only two of the five samples of _I. s. aquinia_ contained small amounts of ithomiolide A (3), whereas PA derivatives were entirely absent from _I. s. derasa_.

**Table 1:** Compounds found in extracts of the androconia of _Ithomia salapia derasa_ and _I. salapia aquinia_. Five individuals of each subspecies were analyzed. Only compounds occurring at least in two individuals of a subspecies are listed. The number before: indicated the number of individuals carrying this compound. The following numbers indicate the range of the relative amount within the samples. The peak group refers to Figure 2.

In contrast, the sesquiterpene α-elemol (8) was exclusively present in all tested individuals of *I. s. derasa*, together with some related minor sesquiterpenes. This sesquiterpene alcohol is likely formed from hedycaryol (7) during GC/MS analysis by a Cope-rearrangement [23, 24], indicating that 7 is likely to be originally present in the hairpencils. That said, we cannot disprove that this rearrangement could also occur in the androconia, such that 7 might also be present in the original volatile bouquet. Hedycaryol is an early product of sesquiterpene biosynthesis, formed by a 1,10-cyclization of the farnesyl-cation 5 obtained from farnesyl pyrophosphate (4). Trapping the cation 6 with water leads to 7, which in turn might rearrange into 8.
Scheme 2. Biosynthetic formation of hedycaryol (7) and α-elemol (8).

The fatty acid ester composition also differed between the two subspecies. Based on their elution order, five groups of compounds were detected, labelled A-E in Figure 2. Groups A and B consisted of saturated and unsaturated C₁₆ and C₁₈ pentenyl esters. These compounds proved to be 3-methyl-3-butenyl esters, which were previously reported in bees [25, 26]. Biosynthetically the alcohol part seems to originate from the terpene building block 3-methyl-3-butenyl (isoprenyl) pyrophosphate. Because isoprenyl pyrophosphate is partly converted to 3-methyl-2-butenyl (prenyl) pyrophosphate during terpene biosynthesis, the presence of prenyl esters could not be excluded. Nevertheless, the two ester types can be readily distinguished by EI-MS.
While 3-methyl-3-butenyl esters of saturated acids have a dominating ion at m/z 69, 3-methyl-2-butenyl esters show ions m/z 68 and 69 of similar intensity (see SI, Figure S2), as reported earlier [26]. This situation changes when a double bond is present in the acid part. In both isoprenyl (9) and prenyl esters (10) ion m/z 69 is now the base peak, but the proportion of m/z 68 is higher in the former esters (Figure 3). Other significant differences can be found in the region around the acylium ions. Monounsaturated prenyl esters show the elimination of methylbutene (M-70, m/z 280 in Figure 3A), the loss of the prenyl group (M-69, m/z 281), and the acylium ion (m/z 263). In contrast, isoprenyl esters lack the M-69 ion, but additionally show acylium+1 and +2 ions (m/z 264 and 265 in Figure 3A).

The location of the double bonds in the unsaturated esters was determined by dimethyl disulfide (DMDS) addition [27, 28]. Because the double bond in the isoprenyl side chain would likely interfere, the esters were first transformed into the respective methyl esters via a microreaction with NaOMe [29]. The following DMDS derivatization revealed the presence of two isomers of each chain length, 9- and 11-hexadecenoate, as well as 9- and 11-octadecenoate (SI, Table S1). Therefore, groups A and B consisted predominately of isoprenyl esters of saturated and two unsaturated C_{16}- and C_{18}-acids. Major components of both subspecies were group D compounds. The peak pair m/z 68/69 including the prominent base peak indicated again isoprenyl esters. The mass spectrum of the saturated compound (Figure 4) showed a small putative M+ ion at m/z 410 and m/z 408 for the unsaturated analogs. A loss of 59/60 amu from the M+ suggested an acetoxy group located somewhere in the chain. The position could not be derived from the mass spectrum. Nevertheless, the transesterified sample discussed before contained methyl hydroxyalkanoates, which allowed easy location of the hydroxy-group position by GC/MS. The ion m/z 103 in the spectra of the three dominating acids confirmed the location of the acetoxy-group at C-3 (see SI, Figure
S3). The locations of the double bonds in the methyl esters were then determined by DMDS derivatization. The prominent ions present in these adducts allowed the localization of the double bonds in the natural products. Surprisingly, double bonds were found at C-11 and C-13, deducible by the ions m/z 145 ([CH₃SC₇H₁₄]⁺), 261 ([CH₃CO₂C₁₁H₂₂SCH₃]⁺), 243 (261-H₂O), as well as 213 (261-H₂O-CH₂O), and m/z 117 ([CH₃SC₅H₁₀]⁺), 289 ([CH₃CO₂C₁₃H₂₆SCH₃]⁺), 271 (289-H₂O) as well as 241 (289-H₂O-CH₂O), respectively (see SI, Figure S4). An isomer with a C-9-double bond present in the simple isoprenyl esters was not detected. The configuration of the double bonds was confirmed to be (Z) as expected, because GC/DD-IR analyses showed a characteristic C-H stretch band at 3004 cm⁻¹ (see SI, Figures S9) [30, 31]. As such, group D consisted of isoprenyl esters of 3-acetoxy-C₁₈-fatty acids, a group of compounds not before described in nature. To confirm this, representative isomers were synthesized.
Figure 3. Mass spectra of A: isoprenyl (3-methyl-3-butenyl) 9-octadenoate (9) and B: prenyl (3-methyl-2-butenyl) 9-octadecenoate (10). Red arrows show differences in the mass spectra differentiating prenyl and isoprenyl esters.
Figure 4. Mass spectra of 3-acetoxy esters. A: isoprenyl 3-acetoxyoctadecanoate (11); B: isoprenyl (Z)-3-acetoxy-13-octadecenoate (12).

Isoprenyl 3-acetoxyoctadecanoate (11) was synthesized according to
Octadecanol was oxidized to octadecanal using o-iodoxybenzoic acid (IBX) [32]. The resulting aldehyde was transformed into β-ketoacid 16 with ethyl diazoacetate and SnCl₂ [33], which upon reduction with NaBH₄ in methanol delivered methyl 3-hydroxyoctadecanoate (17). Transesterification was performed with 3-methyl-3-buten-1-ol using distannoxan catalysis [34]. Final acetylation of the hydroxy esters delivered the target compound prenyl 3-acetoxyoctadecanoate. Comparison of mass spectra and retention index confirmed that the naturally occurring compound was indeed isoprenyl 3-acetoxyoctadecanoate (11).

Major components of both species were the unsaturated analogs of 11. Furthermore, the absolute configuration of the hydroxyesters was unknown. Therefore, an
The enantioselective synthesis of isoprenyl (Z)-3-acetoxyoctadec-13-enoate (12) was performed to verify the structural proposal and to determine the absolute configuration of the natural product (Scheme 4). The commercially available epoxide (R)-22 served as chiral starting material. 1,9-Nonanediol (19) was monobrominated and oxidized with IBX to yield 9-bromononanal 20. A Wittig reaction with pentylyphosphonium bromide resulted in bromoalkene 21 in a 9:1 Z/E-mixture. In the following step, the Grignard reagent of 21 was converted into the respective Gilman cuprate with Cu(I)I for the selective reaction with the epoxide function of (S)-22 [35]. The hydroxyester 23 was obtained in good yield. The following stannoxane induced transesterification and the final acetylation procedure delivered finally 12. The two isomeric natural 3-acetoxyoctadecenyl esters had retention indices of 2678 and 2692, respectively, while synthetic 12 showed an I of 2688 and the corresponding prenyl ester a value of 2729. Therefore, the second eluting ester is isoprenyl (Z)-3-acetoxy-13-octadecenoate, while the earlier eluting one is the 11-isomer.

\[

\]

With chiral material in hand, the absolute configuration of 12 was determined by chiral gas chromatography. Because direct determination of the large esters seemed to be difficult because of the high elution temperatures needed, we reasoned that the
respective methyl 3-hydroxyesters would be much better suited, given the well-known
good separability of these compounds by chiral GC [36]. Therefore, a natural extract
of the androconia and synthetic \((R)-12\) were transesterified with NaOMe as described
above to yield methyl 3-hydroxyoctadecenoates. A synthetic sample of \(rac\)-12 obtained
from \(rac\)-22 was also at hand. The analysis showed that only \((R)-12\) occurs naturally
(Figure 5). Furthermore, the \((Z)\)-configuration of the double bond was confirmed,
because the minor amount of the \((E)\)-isomer present in the synthetic sample did not
coelect with the natural sample. Although only the configuration of natural 12 was
determined to be exclusively \((R)\), it seems likely that the other 3-acetoxy esters also
show this configuration.

![Figure 5](image-url)

**Figure 5.** Separation of the enantiomers of methyl \((Z)\)-3-hydroxy-13-octadecenoate (25) on a chiral \(\beta\)-6-TBDMs hydrodex gas chromatographic phase. A) Natural extract; B) synthetic \(rac\)-25; C) synthetic \((R)\)-25; X: methyl 3-hydroxy-11-octadecenoate; Y: methyl 3-hydroxyoctadecanoate; E: \((E)\)-isomer of \((R)\)-25.
Group E compounds represented bishomologs of \textbf{12}, isoprenyl eicosanoate and isoprenyl 13-eicosenoate, determined by DMDS derivatization. Next to these major esters, minor amounts of related esters occurred in some samples. These include deacylated 3-hydroxyesters, isoprenyl 3-hydroxyoctadecenoates and 3-hydroxyoctadecanoate, occurring in group C. Finally, respective elimination products, e.g. isoprenyl 2,11-octadecadienoate and isoprenyl 2-octadecenoate occurred in group B. The location of the C-2 double bond was verified by DMDS derivatization. Because deactivated bonds such as \(\alpha,\beta\)-unsaturated double bonds are too unreactive for DMDS addition, their location can be verified by mass spectrometric fragments missing 2 amu compared to saturated analogs (see SI, Figure S5) [37]. Hydroxy and \(\alpha,\beta\)-unsaturated esters were not observed during GC of synthetic samples, making an artificial formation during chromatography unlikely.

In addition to the esters, minor amounts of alkanes and alkenes were present, as well as fatty acids. The latter occurred in varying amounts in the samples, maybe depending on variation in quality of the individual sample (see Tables S3 and S4). Acids are also present in other tissues of the butterflies, unlike the esters. Esters were also not detected in wings of female \textit{I. salapia}.

The major components of the androconia were identical in both subspecies (Table 1). Variations were observed between individuals and no defined proportion between saturated and unsaturated esters or between different double bond isomers were detected. Nevertheless, differences were present in the minor components and more volatile compounds (Table 1). Sesquiterpene \textbf{8} is restricted to \textit{I. s. derasa}, whereas ithomiolide A (\textbf{3}) occurred exclusively in some of the \textit{I. s. aquinia} samples. C\textsubscript{16}-isoprenyl esters are exclusively found in \textit{I. s. aquinia}, while Isoprenyl 3-acetoxy-13-eicosenoate, abundant in \textit{I. s. derasa}, occurs only in trace amounts in \textit{I. s. aquinia}. 

17
Discussion

The occasional occurrence of PA derivative 3 in two samples of *I. s. aquinia* may depend on the availability of the PA precursor in the wild. It might be that all individuals devoid of 3 simply had no access to PAs and/or that its absence is a specific trait of *I. s. derasa*. In contrast, elemol/hedycaryol (8) is specific to the latter subspecies. Although sesquiterpenes are common in plants, the occurrence of a single sesquiterpene might hint towards individual biosynthesis in this subspecies or specific take-up, because plant sesquiterpenes usually occur in mixtures. Furthermore, hedycaryol is a quite simple sesquiterpene, needing only one biosynthetic cyclization step from the universal sesquiterpene precursor farnesyl pyrophosphate to arrive at this structure (Scheme 2) [38]. The differences in the Isoprenyl esters reported are present in all individuals tested, pointing to distinct differences in activity of biosynthetic enzymes between the two subspecies.

Fatty acid esters, which were repeatedly reported to occur in androconia and male scent glands of butterflies [39–43], have been proposed to function e. g. as fixatives for more volatile pheromones [39], but their exact function remains mostly unknown. Because of the quite low volatility of the Isoprenyl esters, especially of the major acetoxy esters, olfactory activity seems likely only in close vicinity of the male wings, although the evaporation rate might be increased by erection of the androconia hairpencils (Figure 1). Alternatively, direct or close contact might be needed for detection, probably taking place during contact of the female antennae with the male wings. What this potential signal might indicate remains speculative.

Nevertheless, the unusual location of the double bonds indicate an active function of the isoprenyl esters as a signaling compound. Unsaturated fatty acid derivatives in pheromone glands are typically introduced by desaturases acting on saturated
precursors. In the biosynthetically well-known butterfly genus, *Bicyclus*, a $\Delta^{11}$-desaturase, also often involved in moth pheromone biosynthesis, leads to derivatives of $\Delta^{11}$-C$_{16}$ and C$_{18}$-acids [44]. The fatty acid derivatives present in the male hairpencils of the danaine butterfly *Lycorea ceres ceres* also indicate the presence of a $\Delta^{11}$-desaturase [45]. In contrast, products consistent with $\Delta^{9}$-desaturase activity are present in androconia of the genus *Heliconius* [46]. Unlike these species, *Ithomia* seems to use at least two different desaturases, $\Delta^{9}$ and $\Delta^{11}$, leading to regioisomeric mixtures of isoprenyl esters. The location of the double bonds in the acyl chain of the esters can be explained by a biosynthetic pathway described in Scheme 5. The double bond distribution is consistent with both desaturases acting on palmitic acid, leading to the respective hexadecenoic acids. These acids are the starting point for an additional elongation cycle of the fatty acid biosynthesis, leading en route to 3-hydroxy- and 2-alkenoic acids and finally to 11- and 13-octadecenoic acids. While the latter acid was not observed, 9-octadecenoic acid was present, formed likely by action of the $\Delta^{9}$-desaturase.

3-Acetoxylated fatty acid esters are rarely found as natural products. Ethyl (S)-3-acetoxyeicosanoic acid and longer analogs are produced by the plant *Schizolaena hystrix* [47], but similar compounds from insects are unknown. Related are cactoblastins used as trail-following pheromones by *Cactoblastis cactorum* [48], which represent methyl esters of 3-hydroxy fatty acids acylated at O-3 with another fatty acid. The isoprenyl fatty acid esters are not restricted to the genus *Ithomia* within the Ithomiini. Preliminary analysis has also found that other species, e.g. *Hypothyris anastasia, Hyposcada illinissa, H. anchiala*, or *Melinaea menophilus* contain these compounds in the androconia. In contrast, 9-hydroxynonanoic acid derived acids and esters are currently only reported from *Oleria* [21].
Scheme 5. Proposed biosynthetic pathway of fatty acids leading to the observed regioisomers of the isoprenyl esters. \((Z)-9\)-Hexadecenoic acid is obtained from palmitic acid by a \(\Delta 9\)-desaturase. \((Z)-3\)-Hydroxy-11-octadecenoic acid is an intermediate of the fatty acid elongation cycle. Elimination leads to \((2E,11Z)-2,11\)-octadecadienoic acid (not shown) and after hydrogenation to \((Z)-11\)-octadecenoic acid. A second elongation cycles furnishes \((Z)-3\)-hydroxy-13-eicosenoic acid. Similarly, a \(\Delta 11\)-desaturase gives \((Z)-11\)-hexadecenoic acid and in turn \((Z)-3\)-hydroxy-13-octadecenoic acid. Both desaturases might also act on octadecanoic acid, but only the elongation of \((Z)-11\)-octadecenoic acid leads to \((Z)-3\)-hydroxy-13-eicosenoic acid. The proposed biosynthesis might also take place in form of the conjugated acids, e.g. coenzyme A esters or acyl carrier proteins. Finally, the acids are converted into the isoprenyl esters and the hydroxy acids are acylated.

Conclusion

In summary, we report here a group of esters, never before reported in nature, 3-acetoxyacyl isoprenyl esters from *Ithomia salapia*. Due to their abundance in the androconia and the specialized enzymes needed to produce them, a pheromonal
function, especially at close range, seems to be likely associated with these compounds. Differences in composition between the two subspecies suggest a possible role of the chemical bouquet in reproductive isolation, although other factors, such as wing color pattern, can also act as a reproductive barrier.
